

PROFILES OF WIND DIRECTION AND SPEED IN TURBULENT EKMAN FLOW

CEDRICK ANSORGE, HAUKE WURPS

ABSTRACT. The profiles of wind speed and direction in turbulent Ekman flow are formulated based on asymptotic theory and data from direct numerical simulation. The profile of the streamwise component follows the classical viscous, logarithmic and wake scaling. In the outer layer, the velocity component profiles can be described by an Ekman-spiral with adapted boundary conditions that result in a reduction of the spiral-like rotation. The span-wise component poses a conceptual challenge to the channel-flow analogy in the context of asymptotic matching; it exhibits a mixed scaling in the surface layer, but follows outer scaling for most of the outer layer. Viscous stress scales universally across the boundary layer in inner units while the total stress becomes universal as a function of outer height. This implies a mixed scaling for the turbulent stress and eddy viscosity across the inner layer and convergence to a universal scaling as function of the outer height across the outer layer for increasing scale separation *vide* Reynolds numbers.

1. INTRODUCTION

Wind veer away from its geostrophic direction is (i) due to direct frictional effects in the very vicinity of the surface and (ii) due to turbulence which exerts indirect frictional effects; these effects cause a slow-down of the mean wind reducing the Coriolis force thus turning the wind in favor of the pressure gradient force. Not only does the veering set the frame of reference for surface layer theory, it also has effects at small and large scales. From a large-scale perspective, the veering of wind across the planetary boundary layer determines the amount of cross-isobaric mass-flux, commonly referred to as 'Ekman pumping' (Ekman, 1905), and it is thus a key factor in the life-cycle of large-scale synoptic systems. At the small-scale end, the directional shear of the wind in the upper part of the surface layer may cause a systematic yaw for tall wind power generation devices where blades reach into the Ekman layer, i.e. that part of the boundary layer where the wind starts to turn.

Wind veer in the planetary boundary layer is commonly characterized by the surface veering angle α defined as the angle between the negative surface shear stress τ_{sfc} and the geostrophic wind. Surface veering α and geostrophic drag $Z \equiv u_{\star}/G$, where $u_{\star} \equiv \sqrt{\nu|\tau_{\text{sfc}}|}$, uniquely determine the surface drag τ_{sfc} in a turbulent Ekman flow. In any quantitative description of the surface layer, the friction velocity u_{\star} is the dynamic scale and α defines the alignment of the frame of reference. Knowledge about u_{\star} and α is thus a pre-requisite for any quantitative theory of the surface layer and a first attempt in theoretical quantification was undertaken by Rossby and Montgomery (1935) using integral relations in the boundary layer. Asymptotic similarity theory was later used by Tennekes (1973) and Blackadar and Tennekes (1968), and—based on his seminal direct numerical simulations (DNS) of Ekman

flow-, Spalart, 1989 suggested a modification to take into account effects of low to intermediate Reynolds numbers. Later on, constants were re-evaluated with a focus on the atmospheric boundary layer based on observations (Högström, 1988; Högström, 1996) and numerical modelling (Spalart et al., 2008; Spalart et al., 2009; Ansorge and Mellado, 2014; Ansorge, 2019).

Attempts were also undertaken to obtain profiles of the wind speed: One approach is to match the inner and outer layer at a reference height; Etling (2002) and Emeis (2018) (Sec. 21.10; Eq. 21.48) choose the Prandtl-layer height to match the wind speed profiles, which, however, requires to externally prescribe the veering α at that height. A one-dimensional profile with constant veering is given by Emeis et al. (2007, Sec. 3, Eq. 3.1-3.19).

Gryning et al. (2007) present an extension of the wind-speed profile beyond the surface layer using a neutral reference profile and a stability correction; Kelly and Gryning, 2010, based on a probabilistic representation of stratification, develop a model for the long-term mean windspeed in the atmospheric boundary layer and compare this with observation at different sites; Kelly and Troen, 2016 demonstrate the effect of such improved model for wind-energy applications. In consideration of the large scale separation in geophysical flow, the rotation of the wind in the surface layer is often assumed negligible, and above investigations merely focus on the wind speed; that means, the veering of the wind with height is not described and there is little knowledge on the profile of the span-wise velocity component and the precise shape of the hodograph in the limit of a truly neutral Ekman boundary layer.

Ekman-layer models and two-layer models of the ABL take into account rotational effects at higher altitudes, for instance when the wind speed needs to be evaluated at heights on the order of 100-200 m, a particular concern when it comes to wind-power forecasting (Optis et al., 2014). Despite rotational effects being considered, the formulation of these models for the outer layer and analysis of their performance primarily focuses on wind speed. Still, in 2018, Jiang et al. recognized that the outer part of the Ekman boundary layer receives less attention in comparison with the surface layer and commence in studying the neutral problem by Large-Eddy simulation (LES). They focus on the wind speed and find an extended logarithmic layer when considering the wind speed instead of the shear-aligned component, and they eventually demonstrate by means of an analytical model that this vertical extension of the logarithmic layer may be explained by a transfer of stress to the spanwise velocity component where it is assumed that the shear vector $\tau(z)$ and stress vectors $(\partial_z U, \partial_z V)$ are aligned.

Turbulent Ekman flow is considered here as a conceptual model of the homogeneous, stationary atmospheric boundary layer over a flat surface under neutral stratification. Universal profiles of the wind vector for turbulent Ekman flow not only are a well-described limit for theoretical exploration or higher-order approaches taking into account possible effects of stratification, roughness or other physical complications encountered in the realgeophysical system. While, on first sight, the study of such a strongly idealized case appears as an academic problem, it contains the essence of surface similarity as it is used in most atmospheric models, be it conceptual or numeric ones. For instance, effects of roughness are commonly incorporated by a linear transformation of vertical scale involving the roughness parameter z_0 and for larger roughness also a displacement height (Monin and Yaglom, 1975; Jacobs and Van Boxel, 1988; Högström, 1988); effects of stability are commonly accounted for by

a linearization around the neutrally stratified profile (Monin, 1970; Monin and Yaglom, 1975; Högström, 1988; Högström, 1996; Sakagami et al., 2020). Furthermore, profiles can serve as better initial condition for numerical simulation of the flow, to minimize the length of initial transient periods, or as benchmark for turbulence closures that can be tuned to reproduce the neutral limit case.

Despite the strong simplifications implied by our choice of set-up, there is no straightforward approach to solving this conceptually well-defined problem. Large-Eddy simulation not only needs to be tuned for the surface shear stress and veering angle, but it also relies on sub-grid closures that often assume alignment of the stress with gradients – a questionable pre-requisite when the wind rotates with height. Esau (2004) investigated the representation of the Ekman boundary layer by dynamical subgrid closures and Zikanov et al., 2003 proposed a closure for the wind profile using a linearized representation of the eddy viscosity. Despite advances in analysis of this simplified set-up (Jiang et al., 2018), there is yet insufficient understanding for a quantitative generalization of the results to arbitrary external forcing (manifest in variation of the Reynolds number) – and indeed the fundamental questions pertaining to such relatively simple dynamics of turbulence are not reflected in the research foci of LES for the ABL over the past 50 years (Stoll et al., 2020).

At the same time, an increasing amount of high-quality and high-resolution data from turbulence-resolving approaches is emerging due to recent advances in high-performance computing and its application to geophysical problem sets; the geophysical range of scale separation, however, is—and it will remain so for the foreseeable future—out of reach for such simulation (Dimotakis, 2005). Here, the routinely employed concept of Reynolds-number similarity can help. It postulates the existence of “*fully developed turbulence*” believed to occur for a sufficiently large but finite Reynolds number” (Barenblatt and Goldenfeld, 1995). (Already in 1998, this in fact lead Moin and Mahesh to the question *how high a Re is high enough?*) In fully developed turbulence certain statistics such as dissipation (Dimotakis, 2005) or profiles of mean velocity (Barenblatt, 1993) become independent of the Reynolds number when scaled appropriately while other statistics, such as the near-wall maximum in velocity fluctuation depend on Re (Baars and Marusic, 2020) and external interfaces may exert an impact on near-wall scaling (Silva et al., 2014). It appears that for certain statistics in Ekman flow, fully-developed turbulence is reached with the Reynolds numbers that became possible with the increasing capabilities of supercomputing over the past decades.

This paper exploits the robust features of mean velocity profiles from direct numerical simulation across a range of Reynolds numbers to formulate both the streamwise and span-wise components of the mean velocity vector as a function of the Reynolds number.

2. PROBLEM FORMULATION AND NUMERICAL APPROACH

We consider here incompressible, turbulent Ekman flow, that is, the turbulent flow over a flat rotating plate, as a physical model for the truly neutral atmospheric boundary layer (ABL). The f-plane approximation is applied such that rotation only acts on horizontal velocity components; we thus neglect rotational effects on the horizontal components of velocity and dynamical effects due to latitudinal variation of the rate of rotation.

2.1. Notation and Governing Equations. The dimensional velocity vector of the numerical simulations is $\underline{U} = (U_1, U_2, U_3) = (U, V, W)$ over the coordinate system $Oxyz$, where an approximate alignment (plus/ minus few degrees) of the direction Ox with the surface shear stress is achieved. The coordinate Oz points away from the wall, and Oy points in the span-wise direction normal to Oxz . For analysis of the results, we use two coordinate systems that are (i) exactly aligned with the surface shear stress

$$(1a) \quad \underline{\tau}_{\text{sfc}} = \begin{pmatrix} \tau_x \\ \tau_y \\ \tau_z \end{pmatrix} = -\nu \left(\frac{\partial U}{\partial z} \hat{e}_x + \frac{\partial V}{\partial z} \hat{e}_y \right)$$

and labelled by an upper index α as in \underline{U}^α for the velocity vector, and (ii) the coordinate system aligned with the free-atmosphere geostrophic wind labelled by an upper index G as in \underline{U}^G . We denote the normalized modulus of the surface friction by

$$(1b) \quad u_* = \sqrt{\|\underline{\tau}_{\text{sfc}}\|}$$

and let $Z_* = G/u_*$; the surface veering angle α_* is the angle between $\underline{\tau}$ and the geostrophic wind

$$(1c) \quad \alpha_* = \sphericalangle(\underline{G}, \underline{\tau}_{\text{sfc}}).$$

Analogously, we denote the height-local veering of the wind $\alpha(z) = \sphericalangle(\underline{G}, \underline{U}(z))$.

We consider the incompressible Navier–Stokes equations for the three velocity components on the f-plane in a framework that is governed by the physical parameters (i) geostrophic wind magnitude $G = \sqrt{G_1^2 + G_2^2}$ (where $\mathbf{G} = (G_1, G_2, 0)$ is the geostrophic wind vector), (ii) Coriolis parameter f (representing the angular rotation), and (iii) kinematic viscosity ν . These yield a Reynolds number as non-dimensional parameter governing the system. We use the geostrophic wind as velocity and the Coriolis parameter f as time scale for the non-dimensional framework. This implies the Rossby radius $\Lambda_{\text{Ro}} = G/f$ as length scale, such that one Reynolds number governing the problem reads as

$$(2) \quad \text{Re}_\Lambda = \frac{G\Lambda_{\text{Ro}}}{\nu}.$$

The scales used in defining Re_Λ loose their relevance in describing the turbulent state of the flow. The friction Reynolds number

$$(3) \quad \text{Re}_\tau = \frac{u_* \delta}{\nu} = \delta^+ = \frac{\text{Re}_\Lambda}{Z_*^2},$$

where $\delta = u_*/f$ and we use a superscript '+' to denote normalization by inner turbulence scales (u_*, ν) . Re_τ is suitable to compare the turbulence scale separation also to other wall-bounded flow geometries such as rotating or non-rotating channel, pipe, or Couette flow.

The governing equations non-dimensionalized by G , f , and Λ_{Ro} read as

$$(4a) \quad \frac{\partial u_i}{\partial t} = \frac{\partial \pi}{\partial x_i} - u_j \frac{\partial u_i}{\partial x_j} + \epsilon_{ij} (u_j - G_j) + \frac{1}{\text{Re}} \frac{\partial^2 u_i}{\partial x_j^2}$$

$$(4b) \quad \frac{\partial u_j}{\partial x_j} = 0,$$

TABLE 1. Direct numerical simulation datasets used in this work

where $u_i = U_i/G$ are the non-dimensional components velocity, π is non-dimensional pressure, and $g_j = G_j/G$ are non-dimensionalized components geostrophic wind (with $g_1^2 + g_2^2 = 1$ by construction). These equations are solved inside a bounded cube of size $L_x \times L_y \times L_z$ with periodic boundary conditions in the lateral directions Oxy , a no-slip–no-penetration boundary at $z = 0$, and a no-penetration, free-slip boundary at $z = L_z$.

2.2. Numerical Simulations. The problem is solved numerically by tLab¹, an open-source tool-suite to simulate and analyze turbulent flows. We use here a fourth-order–five-step Runge–Kutta integration and sixth-order compact schemes for spatial derivatives in all directions. The incompressibility constraint is enforced by a fractional step approach where the Poisson equation for the pressure field is solved to machine accuracy using a combined spectral/compact approach as described in Mellado and Ansorge (2012).

Simulations used here are shown in Tab. 1. We extend an existing set of simulations for $\text{Re}_\Lambda \in \{125\,000; 281\,250; 500\,000\}$ (gray shading; cf. Ansorge and Mellado, 2014; Ansorge and Mellado, 2016) by new simulations at higher Reynolds numbers up to 1.28×10^6 with a horizontal domain extent up to 3.3×10^4 viscous units. In total, this yields one order of magnitude variation in terms of the scale separation in the boundary layer.

3. SCALING BEHAVIOR OF THE FLOW FOR Re_τ UP TO 3000

The generalization of profiles to arbitrary Reynolds numbers requires sufficient scale separation in the simulations to not only quantify the effect of the Reynolds number on low-order flow statistics, but also assess the corresponding rate-of-change to eventually allow for an extrapolation of the findings. While the simulations available give confidence in a first-order representation of the turbulent problem, the estimation of higher-order effects such as the dependency of the Reynolds number requires a broader scale separation that is made available by the two new simulations for (cf. Tab. 1). Data at such scale separation has been obtained previously (cf. Spalart et al., 2008; Spalart et al., 2009), but we also need high confidence with respect to the convergence of simulation data for slow oscillations and with respect to sampling convergence, which translates to two further requirements on the data: First, data should be free of artifacts from long-term oscillations across the vertical extent of the domain—primarily, simulations should be free of effects originating from the inertial oscillation; this is achieved here by

¹<https://github.com/turbulencia/tlab>

TABLE 2. Bulk characterization of the simulations for different Reynolds numbers Viscous Reynolds number Re , friction Reynolds number Re_τ , friction velocity u_* , surface veering angle α_* , normalized boundary layer depth δ_{95}/δ inner normalization of vertically integrated TKE, outer normalization of vertically integrated dissipation.

Re	$\delta^+ = \text{Re}_\tau$	u_*	α_*	δ_{95}/δ	$f u_*^{-3} \int_0^\delta \epsilon dz$	$G^{-3} \int_0^\delta \epsilon dz$
500	479	0.0619	25.5	0.66	0.88	1.31
750	886	0.0561	21.0	0.65	0.90	1.34
1000	1403	0.0530	18.8	0.62	0.92	1.30
1300	2122	0.0501	17.9	0.59	0.85	1.24
1600	2978	0.0482	17.2	0.61	0.91	1.21

replacing the mean value of the three-dimensional velocity fields by the time mean over a whole inertial oscillation. Second, high accuracy is also needed in terms of the statistical convergence of averages, bulk measures and large-scale structures; this requires a domain size $L_x > \mathcal{O}(\delta_{95})$. We use here $L_x = L_y = 1.08\Lambda$ for cases with $\text{Re} \leq 1000$ and $L_x = L_y = 0.54\Lambda$ for $\text{Re} \geq 1300$ which corresponds to $L_x/\delta_{95} \approx 25$ for $Re_D = 500$ and $L_x/\delta_{95} \approx 18$ for $Re_D = 1300$.

Bulk parameters of the simulations are given in Tab. 2. The surface stress is characterized by u_* and α_* in relation to the geostrophic wind vector and discussed in more detail as the drag law below in Sec. 4.1 (we find the expected slight decrease of u_* and α_* with increasing Re). The boundary-layer height estimated from the 95% stress reduction, δ_{95} , is around 0.6δ to 0.66δ . Interestingly, the integrated TKE $\int_0^\delta \epsilon dz$ stays constant when normalized by the friction velocity u_* while the integrated dissipation $\int_0^\delta \epsilon dz$ exhibits inviscid scaling when normalized by the magnitude G of the geostrophic wind. (TKE and dissipation normalized as $fG^{-3} \int \epsilon dz$ and $u_*^{-3} \int \epsilon dz$, exhibit substantial dependence on Re for the variation of u_* .) This indicates that the bulk dissipation is governed by the forcing G -irrespective of Re . Changes in Re , however, affect the level and organization of turbulence, and the parameter representing this dependency is the friction velocity u_* which describes the turbulence production processes in the surface layer, in particular in the buffer layer.

Velocity profiles in inner and outer units (Fig. 1a,b) are in accordance with previous work (Coleman et al., 1992; Spalart et al., 2008; Spalart et al., 2009; Ansorge and Mellado, 2014; Ansorge, 2019): The profiles of the shear-aligned streamwise velocity component are well-collapsed for the Reynolds numbers investigated below $z^- \approx 0.15$ (circles in Fig. 1a); the logarithmic law is appropriate for $50 < z^+ < 0.15\text{Re}_\tau$, where $z^+ = \text{Re}_\tau z^-$. While the profiles $U^{\alpha*+}(z^+)$ diverge between different Re beyond $z^- = 0.15$, the corresponding profiles $U^{\alpha*}(z^-)/u_*$ agree closely, irrespective of Re which illustrates the inner–outer scale-duality in this external flow. It is noteworthy that also in the outer layer of the flow, u_* (not the magnitude the geostrophic wind speed G) is the governing velocity scale for inviscid, i.e. Re -independent, normalization. [WHY? cf. TKE/Dissipation normalization above] No collapse in inner units is found for the profiles of spanwise velocity $V^{\alpha*+}(z^+)$; When normalized in outer units, the profiles of spanwise velocity $V^{\alpha*}(z^-)/u_*$ agree

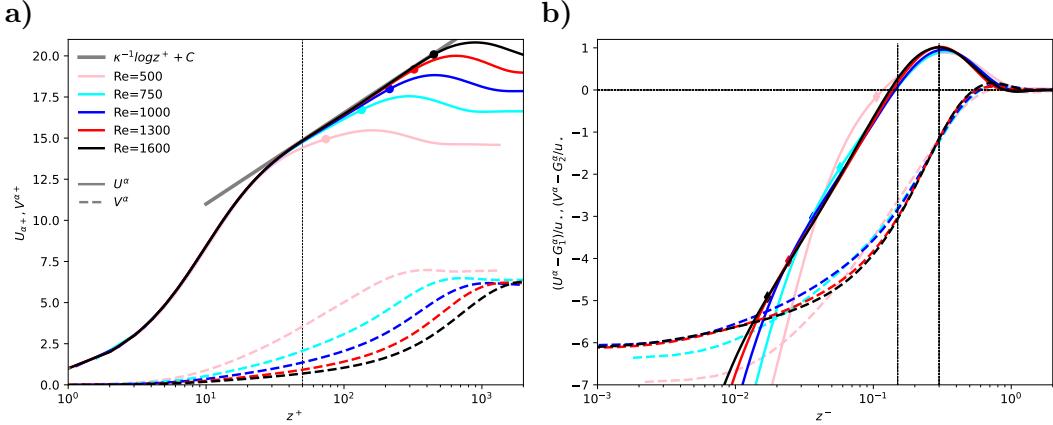

FIGURE 1. **a)** Shear-aligned velocity profiles in inner units; **b)** Shear-aligned velocity deficit in outer units; circles mark the height $z^- = 0.15$; dashed line gives the best logarithmic fit to the data.

well beyond $z^- \approx 0.3$ whereas the profiles of the streamwise component collapse also within the overlap layer that extends much closer down to the surface (circles in Fig. 1b). While low-Re effects appear to be present for $\mathcal{O}(Re) < 10^3$, the spanwise component appears to converge to an Re-independent limit within the range of scale separation considered here.

The normalized viscous stress

$$(5a) \quad S_{\text{visc}} = \nu \sqrt{\left(\frac{\partial U}{\partial z} \right)^2 + \left(\frac{\partial V}{\partial z} \right)^2}$$

exhibits universal scaling when considered as $S_{\text{visc}}^+(z^+)$ (Fig. 2c); this normalization is also appropriate in the outer layer where the viscous stress is, however, small. Small deviations from the universal profile are observed for the smallest Reynolds number $Re = 500$; we attribute these to low-Re effects in the only transitionally turbulent flow ($Re_\tau = 479$). In contrast to the viscous stress, the total stress follows outer normalization, i.e. $S^+(z^-)$ is universal; a discrepancy in the inner layer does not occur as the total stress is approximately constant in the viscous and buffer layer, and a rescaling of the height would have no effect there; above, outer scaling is appropriate for the well-established dynamics in the overlap region of inner and outer layer. This, however, implies a mixed scaling for the turbulent stress,

$$(5b) \quad S_{\text{turb}} = \sqrt{\bar{u}w^2 + \bar{v}w^2}.$$

Indeed, S_{turb} only follows inner normalization below $z^+ \lesssim 20$ (where the turbulent contribution is negligible). In the outer layer, where $S_{\text{visc}} \rightarrow 0$, S_{turb}^+ follows outer normalization for $z^- \gtrsim 0.15$ —with increasing accuracy for larger Re and larger distance from the surface. In the overlap region, i.e. for $z^+ > 20$ and $z^- < 0.15$, the mixed scaling for the turbulent stress can be expressed as

$$(5c) \quad S_{\text{turb}}^+(z^+, Re_\tau) = S^+(z^-) - S_{\text{visc}}^+(z^+),$$

where $z^- = z^+/Re_\tau$.

The Eddy viscosity plays a crucial part when modelling profiles and the vertical transport in turbulent flow. In analogy to the Fick-law for molecular diffusion,

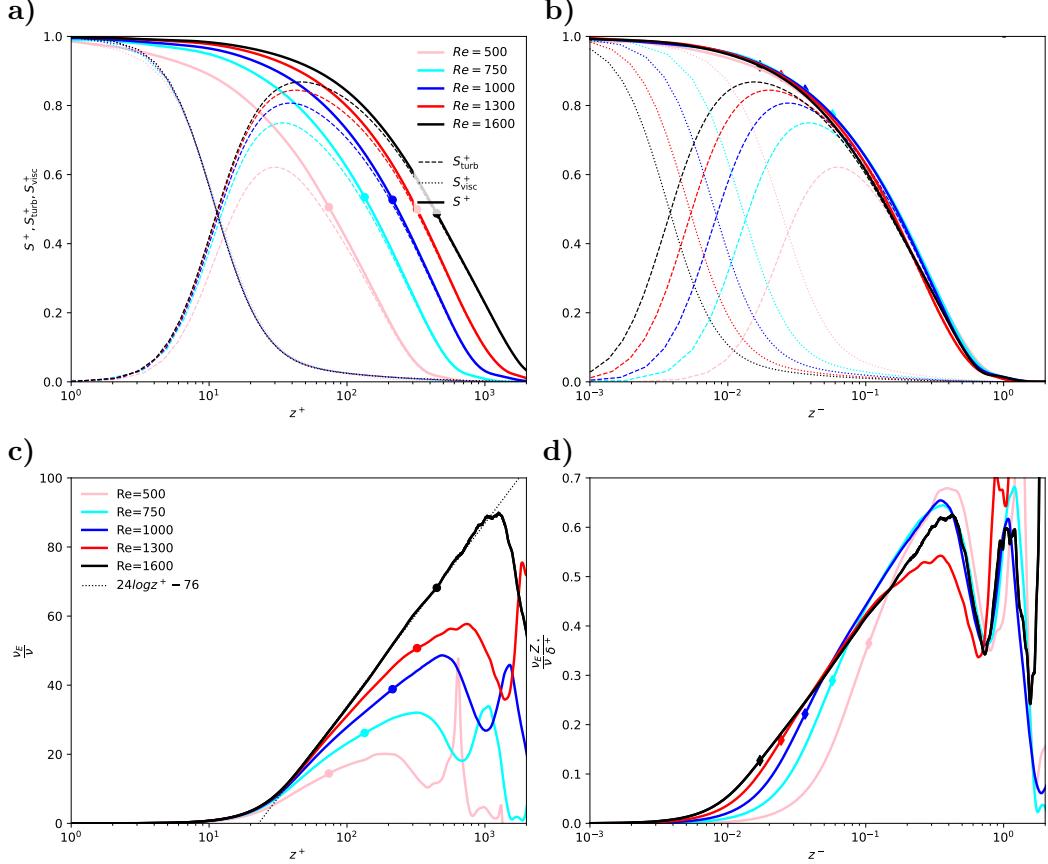

FIGURE 2. **a-b)** Profiles of the turbulent stress S_{turb}^+ (solid), the viscous stress S_{visc}^+ (dotted), and the total stress, $S^+ = S_{\text{visc}}^+ + S_{\text{turb}}^+$ (dashed) as a function of inner height **(a)** and outer height **(b)**. **c-d)** Normalized eddy viscosity ν_E (solid) plotted versus inner **(c)** and outer height **(d)**. Different colors are for different Reynolds numbers (cf. Tab. 1). Circles in **(a)** and **(b)** denote the height $z^- = 0.15$, diamonds in **(c)** and **(d)** are for $z^+ = 50$ as in Fig. 1.

the eddy diffusivity is the effective diffusivity that yields the turbulent transport S_{turb} based on the strain rate. For the symmetries in the flow (horizontal homogeneity, and $W = 0$), it is

$$(5d) \quad \nu_E = \frac{S_{\text{turb}}}{\sqrt{\left(\frac{\partial U}{\partial z}\right)^2 + \left(\frac{\partial V}{\partial z}\right)^2}} = \nu \frac{S_{\text{turb}}}{S_{\text{visc}}}.$$

The inner normalization of ν_E is obtained by division through the molecular viscosity, and it is $\nu_E^+ = \nu_E/\nu = S_{\text{turb}}/S_{\text{visc}}$. Under this normalization, the profiles of eddy viscosity collapse below $z^+ \approx 20$ with a tendency towards better collapse at higher z^+ (up to $z^+ \approx 50$ for $Re = 1600$; Fig. 2b). In the outer layer, the eddy viscosity is characterized by a distinct minimum at $z^- \approx 0.6 - 0.8$, and we find that the following mixed normalization of ν_E by the geostrophic wind and friction velocity

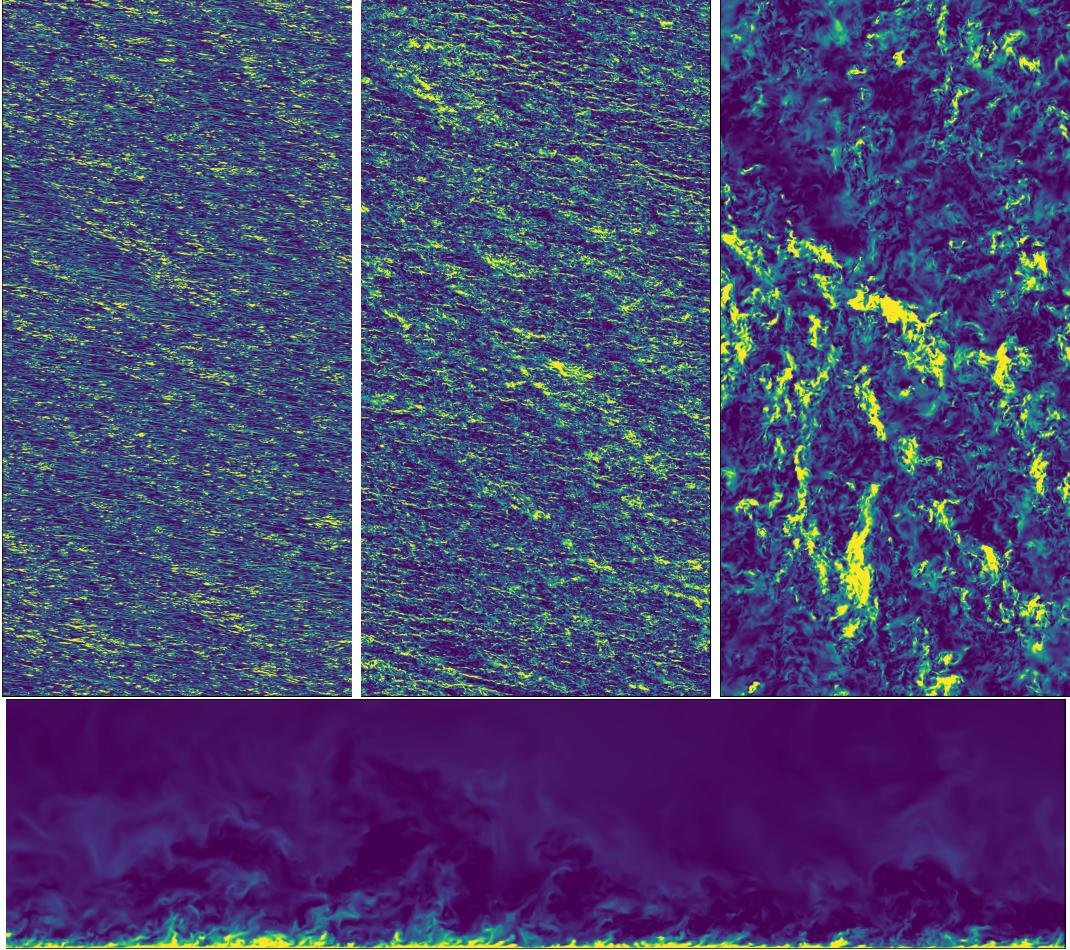

FIGURE 3. horizontal slices of turbulence kinetic energy in the Buffer layer ($i=10$), logarithmic Layer ($i=100$), and outer layer ($i=400$); coloring between percentiles 4 and 96 of the respective image. Lower panel:streamwise–vertical intersect through the domain

collapses the value of ν_E at this minimum (cf. Fig. 2d):

$$(5e) \quad \nu_E^- = \nu_E^+ \frac{Z_\star}{\delta^+} = \nu_E \frac{1}{\nu} \frac{G}{u_\star u_\star \delta} = \nu_E \frac{G f}{u_\star^3}.$$

Substantial variation of the profiles is, however observed below and above this minimum for different Re which illustrates that this normalization is probably not generally appropriate across the outer layer.

The organization of the flow is depicted in terms of the turbulence kinetic energy in Fig. 3. In vicinity of the wall, at $y^+ \approx 10$, (Fig. 3a), elongated streaks aligned with the surface shear stress dominate. Moving away from the wall, to $y^+ \approx 150$ (well within the logarithmic region), the structures are larger and more isotropic, but they are still largely aligned with the surface shear stress. In the upper part of the outer layer, around $y^+ \approx 1000$, no clearly visible signature of the surface veering direction is found, and intense TKE structures (bright yellow) are organized on a large spatial scale with with weaker eddies (greenish structures) and quiescent regions in between.

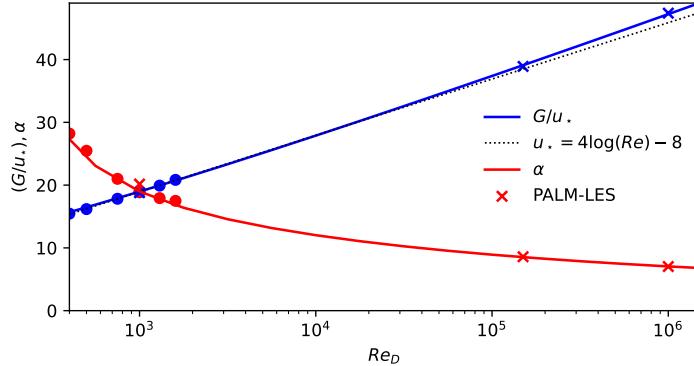

FIGURE 4. Variation of geostrophic drag, Z_* , and surface veering, α_* , with Reynolds number according to the theory by Spalart et al. (1989) and as estimated from DNS data

4. TOWARDS A UNIVERSAL VELOCITY PROFILE FOR THE TURBULENT EKMAN LAYER

We now turn to the formulation of a general velocity profile that is fully determined by the only parameter of the idealized problem, namely a Reynolds number representing the scale separation or geometric size of the problem. This precludes a drag law with wherewith we begin this section (4.1). Based on the scaling arguments put forward in Sec. 3, we then develop a formulation of the wind vector in the Ekman layer (Sec 4.2) and separately for the streamwise (Sec. ??) and spanwise components (Sec. ??) in the overlap and inner regions.

4.1. Drag-Law. A drag-law for Ekman flow determines two key parameters of the flow as a function of Reynolds number alone. These are, first, the modulus of the surface friction normalized by the geostrophic wind forcing, u_* and, second, the direction of surface shear stress, α_* , also termed wind veering. A non-zero veering of the wind is a rather special case in comparison with most turbulent flows considered in an engineering context, and it confronts us with a situation where the most appropriate coordinate system for analysis (namely that aligned with the surface shear stress) is a priori unknown. We compare our DNS data against a semi-empirical drag-law based on integral consideration Spalart, 1989 and find, as demonstrated in previous work Ansorge and Mellado, 2014, excellent agreement in the range $400 < \text{Re} < 1600$, representing a factor of 16 in variation of viscosity.

We also find that the solution of the transient equation involved in estimation of u_* for a given Reynolds number Re_D is approximated reasonably by the formulation

$$(6) \quad u_* = 4 \log(\text{Re}_D) - 8$$

which quantifies the 'weak' dependence of u_* on the Reynolds number as an approximately logarithmic one, at least for problems with a scale separation on the order that is relevant to geophysical problems ($Re_D < 10^8$).

4.2. Profile in the Ekman layer. Formulations for the outer layer that take into account the rotation (and thus deviation from the channel-flow analogy) need to be matched to the framework of surface similarity. A smooth transition from the

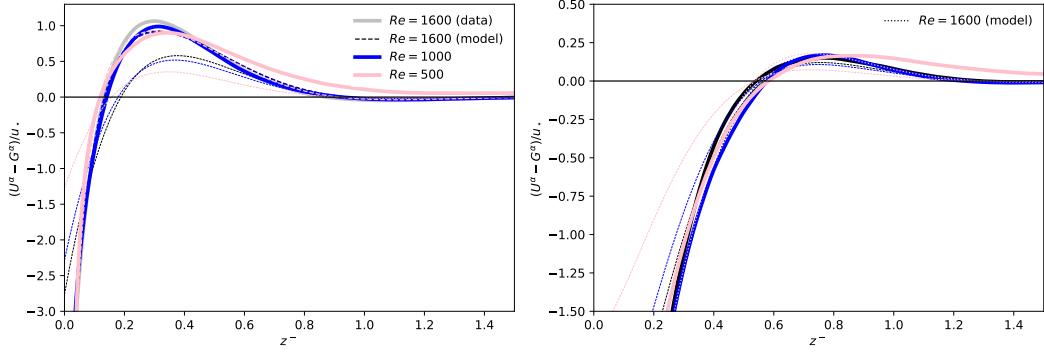

FIGURE 5

inner layer to the Ekman layer, where the wind is characterized by a turning of its mean direction, is not easily achieved. Optis et al., 2014, for instance, define an “effective geostrophic wind vector that has the same magnitude of the observed surface geostrophic wind and is rotated by the angle α [their nomenclature]” to overcome the unsteady transition when coming approaching the Ekman layer from below. While such rotation of the wind vector is *a posteriori* justified by the observational data that the model outcomes are compared to, we understand this as the manifestation of a mismatch between the theoretical treatment of the inner and outer layer of turbulent Ekman flow. The outer layer of Ekman flow is characterized by a turning of the wind velocity and the super-geostrophic maximum that is sustained by momentum convergence at the inflection point of the velocity profile. The super-geostrophic maximum of streamwise velocity and a secondary minimum aloft the bulk-turbulent part of the boundary layer are well-described by a classic Ekman spiral with adapted boundary conditions and a shift in reference height.

4.3. Streamwise Velocity Component. For the streamwise velocity profile (that in non-rotating flows due to the geometry is always aligned with the surface shear stress), well-established theories exist for various regimes according to their distance from the wall and the relative role of viscosity, turbulence and interaction with the outer region of the flow with the logarithmic law for the mean velocity as a central anchor point.

In immediate vicinity to the surface, local turbulent mixing cannot occur for the no-slip/no-penetration boundary condition, and the mean velocity is described by a viscous profile of the form

$$(7a) \quad (U, V)^{\alpha\star+} = (z^+, 0)$$

where the direction of the velocity points into the exact opposite direction of the wall shear stress τ . In absence of roughness elements and for small roughness ($z_0^+ < 5$), this linear regime is known as viscous sub-layer Foken, 2002; Foken et al., 1978. In fact, this law of the wall has no degree of freedom given the drag, i.e. once u_\star and α_\star are defined. However, theoretical foundation is lacking for the exact shape of the velocity profile in the buffer layer; though crucial for turbulence production, it is commonly understood as a transition region between the linear profile at the surface and the logarithmic profile aloft. A pure blending from the linear velocity profile into the logarithmic one is, however, not reasonable as both the linear and logarithmic

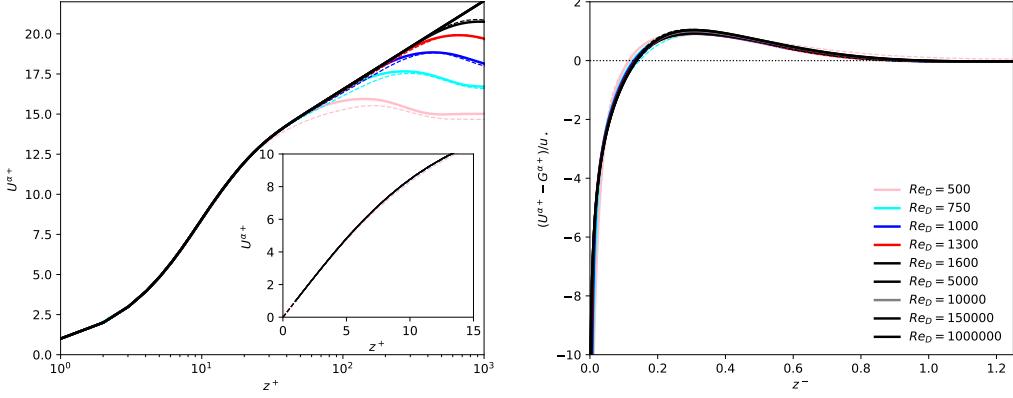

FIGURE 6. Shear-aligned profiles of velocity components $U^{\alpha*+}$ in inner (left) and outer (right) units.

profile overestimate the velocity in the buffer layer. We therefore introduce a higher-order compensating term into the linear profile before blending it into the logarithmic law:

$$(7b) \quad U_{\text{inner}}^{\alpha*+} = \frac{y^+ + \gamma_4(y^+)^4 + \gamma_6(y^+)^6}{1 + \gamma_6/u_{\text{ref}}(y^+)^6},$$

where the fourth- and sixth-order terms in the nominator are designed to fit the profile below $y^+ \approx 10$ and the sixth-order correction in the denominator limits the growth of u_{inner} for large y^+ .

In the logarithmic region, we use the profile

$$(7c) \quad U_{\log}^{\alpha*+} = \frac{1}{\kappa} \log y^+ + C$$

with the von-Kármán constant $\kappa = 0.416$ and the boundary condition $C = 5.4605$.

4.4. Spanwise velocity component. The background rotation and associated veering of the surface wind implies a non-zero profile for the span-wise velocity which challenges the conventional assumptions related to the so-called channel-flow analogy: While the universal profiles in vicinity of the wall implies that the profile be zero or at least small with respect to the streamwise component, the veering requires a value of $V_{top} = U_G \sin \alpha_*$ in the free stream (and thus also at the top of the boundary layer if we assume that substantial velocity gradients are confined to the turbulent part of the flow). This is commonly shown in terms of velocity hodographs aligned with the outer, geostrophic flow (cf. Fig. 8) and normalized by the geostrophic wind. Thus, the drag-law already implies three important properties of these hodographs, (i) the boundary conditions at the surface, (ii) the boundary condition at the top, and (iii) the inclination of the hodograph at the origin by the

surface veering:

$$(8a) \quad \underline{U}^G(z=0) = 0,$$

$$(8b) \quad \underline{U}^G(z \mapsto \infty) = \underline{G}^G = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$$

$$(8c) \quad \left. \frac{\partial V^G}{\partial U^G} \right|_{z=0} = \sin \alpha_*$$

Outer scaling of the velocity profile further implies that the velocity deficit of the spanwise component $V^{\alpha*} - G^{\alpha*}$ be a universal function of the outer height z^- , i.e.

$$(9) \quad V^{\alpha*} - G^{\alpha*} = f_V^{\alpha*}(z^-).$$

Interpreting the shear-aligned spanwise velocity deficit $f_V^{\alpha*}(z^-)$ as a signature of outer rotation may lead one to conclude that this universal function is appropriate down to the surface—irrespective of the Reynolds number. This cannot be the case for the variation of $f_V^{\alpha*}(z^-)$ across the boundary layer (i.e. between $0 < z^- < 1$) must fulfill the drag law and boundary conditions; at the same time, the weak dependence of α_* and u_* on Re implies this range depends on Re .

Outer Layer. In the outer region of the flow (for $z^- \mapsto 1$), $f_V(z^-)$, should govern the spanwise velocity profile which indeed is supported by our DNS data (Fig.7): The deficit is close to zero for $z^- \gtrsim 1$, and can be approximated by a logarithmic profile in the range $0.15 \lesssim z^- \lesssim 0.4$. The slope of this profile is best fit by $\kappa_V = 0.836(1 + 150/Re_D)\kappa$, where the correction term for low Reynolds number may be omitted for $Re_D \gg 1000$. Based on Fig. 7, we pick the offset as a constant fraction (0.906) of $V_G^\alpha = Z_* \sin \alpha$, i.e

$$(10a) \quad V_{\log}(z^-) = \frac{1}{\kappa_V} \log \left(\frac{z^-}{0.4} \right) + 0.906 V_G^\alpha.$$

The eventually converged simulations at intermediate Re_D (where the DNS could be run over several inertial periods) exhibit a super-geostrophic maximum (positiv velocity deficit) in the span-wise component. This maximum is not present or less pronounced for the simulations at higher Re where closer analysis reveals that the velocity profiles in the outer layer are still subject to a small though finite adaptation process on the inertial time scales $2\pi/f$ due to the relatively short time span for which these cases could be simulated. While there is no physical model for this wake region that leads to an analytical velocity profile formulation in the span-wise direction, an error-function transition from the outer logarithmic law to the boundary condition provides a reasonable fit:

$$(10b) \quad V_{\text{outer}}(z^-) = (1 - w_V) V_{\log}(z^-) + w_V V_G^\alpha$$

with

$$(10c) \quad w_V = \frac{\operatorname{erf}[\xi_{\text{outer}} \log(z/z_{\text{ref}})] + 1}{2}$$

where ξ_{outer} is a transition scale that defines the width of the wake region and z_{ref} defines the height. Based on the DNS data, we choose $\xi_{\text{outer}} = 2$ and let z_{ref} such that $V_{\log}(z_{\text{ref}}) = 0.98 V_G^\alpha$. There is, however, a degree of ambiguity in the exact choice of these parameters due to the imperfect convergence of the DNS data to the statistical equilibrium. **Inner Layer.** It is important to note that the logarithmic layer observed here for the spanwise velocity does not coincide with the log-region of the streamwise velocity but is rather a ‘continuation’ through the outer layer. This is

consistent with the recent finding of a second log-region in the outer region of Ekman flow (... et al. (incl. Sullivan), JAS 2019). Below this region, the gradients in spanwise velocity are rather small and the span-wise velocity monotonically approaches its surface boundary condition $V(z = 0) = 0$. While the streamwise velocity follows a universal inner scaling that has acquired its universal, Re -independent shape for $Re_D > \mathcal{O}(10^3)$, the span-wise component that defines how the velocity vector veers when the surface is approached, does not collapse in inner units, and there is, most importantly no sign of convergence even at the highest Reynolds numbers for which simulations were carried out. Even though the simplest assumption $V = 0$ is reasonable for the lower part of the surface surface layer ($z^- < 10^{-3}$), it does not appropriately capture the profile in the rest of the surface layer:

First, $V = 0$ implies a discontinuity in the velocity profile at $z^- = 0.1$, where the outer scaling found above yields a finite value at geophysical Re , i.e. there is non-zero veering in the upper part of the surface layer—as is well-known also from field observation. Second, the layer around $z^- = 0.1$ is crucial to obtain the characteristic and well-established shape of the hodographs as the layer where V sets in marks the ‘maximum’ of V^- vs. U^- . This illustrates that the higher-order (in terms of the channel-flow analogy where $V = 0$) correction follows a mixed scaling when the surface is approached which has been demonstrated for higher-order terms in other types of flow (Mellado et al., 2016).

The scale for the magnitude of the span-wise velocity component is $u_* \sin \alpha$. Based on our DNS data, we suggest that the Reynolds number scaling of this velocity-magnitude scale is captured by $Re_\tau^{-1/2}$ which is indeed known from the generalization of higher-order statistics, such as turbulent fluxes in the inner layer (Marusic et al., 2013) that also follow a mixed scaling in the inner layer. We then parameterize the spanwise velocity at 10 wall units as anchor point in the inner layer:

$$(11a) \quad V_{10} \equiv V(z^+ = 10) = 750 \frac{u_* \sin \alpha}{\sqrt{Re_\tau}}.$$

This leaves us with three fixed points of the velocity profile in the inner layer, namely (i) the boundary condition $V_0 = 0$, (ii) V_{10} at $z^+ = 10$, and (iii) the lower end of the logarithmic profile at $z^- = 0.1$ where the latter two are semi-empirically estimated from DNS data. In absence of well-established scaling considerations for the span-wise velocity, the choice of profile fits joining these three points is indeed arbitrary, but we can resort to the DNS data for an empirical approach and find that a square-root profile fits $V(z^+)$ in the surface layer. A linear profile for V is employed in the viscous sub-layer. Based on the physical extent of the viscous sub-layer in Ekman flow around five wall units (Foken, 2002; Ansorge, 2019), we choose $z^+ = 5$ to transition from one to the other and note that V is already very small at this height. The span-wise velocity profile in the surface layer is then estimated as

$$(11b) \quad V(z^+) \Big|_{\text{inner}} = \begin{cases} a_1 z^+ & ; \quad z^+ \leq 5 \\ b_1 + b_2 \sqrt{z^+} & ; \quad 5 < z^+ < Re_\tau/10 \end{cases},$$

with b_1 and b_2 estimated such that

$$(11c) \quad \begin{aligned} \frac{V(z^+ = 10)|_{\text{inner}}}{V(z^+ = Re_\tau/10)|_{\text{inner}}} &= \frac{V_{10}}{V_{\text{outer}}(0.1)} \Rightarrow \begin{cases} b_2 = \frac{V_{\text{outer}}(0.1) - V_{10}}{\sqrt{Re_\tau/10} - \sqrt{10}} \\ b_1 = V_{10} - \sqrt{10}b_2 \end{cases} \end{aligned}$$

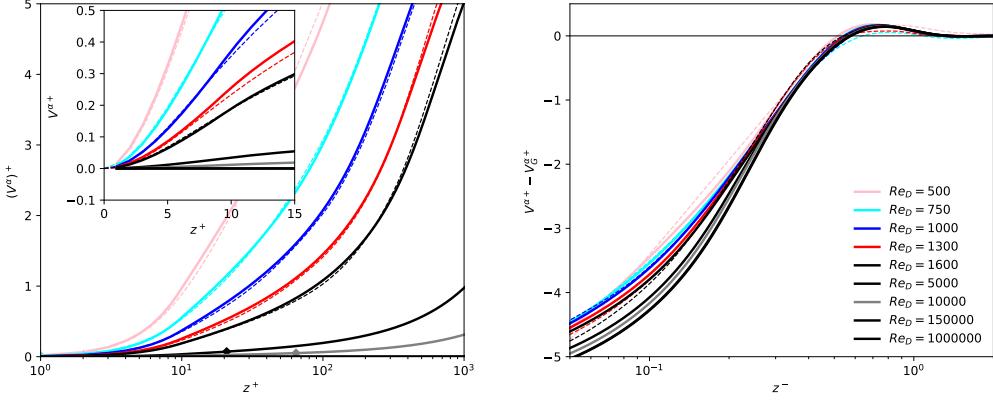

FIGURE 7. Profiles of shear-aligned span-wise velocity $(W^\alpha)^+$ versus inner and outer height. Dashed lines show DNS data, thick, opaque lines are from the semi-empirical theory developed above.

We then estimate α from the matching condition at $z^+ = 5$, i.e.

$$(11d) \quad 5a = b_1 + \sqrt{5}b_2 \Rightarrow a = \frac{1}{5} \left[V_{10} + (\sqrt{5} - \sqrt{10}) \left(\frac{V_{\text{outer}} - V_{10}}{\sqrt{Re_\tau/10} - \sqrt{10}} \right) \right].$$

Matching region. While the profile composed of $V_{\text{inner}}(z^+ \leq 0.1Re_\tau)$, $V_{\text{outer}}(z^- > 0.1)$ is continuous, it is not smooth at $z^- = 0.1$, i.e. at the transition from power-law ($V \propto \sqrt{z^+}$) to logarithmic scaling. To alleviate this issue, we use a second-order polynomial for transition from the inner to the outer layer in the range $z_{\text{low}} < z < z_{\text{up}}$ such that

$$(11e) \quad V_{\text{trans}}(z^-) = V_{\text{inner}}(z_{\text{low}}^+) + \Delta V (az_{\text{arg}} + b(z_{\text{arg}})^2)$$

with $\Delta V = V_{\text{outer}}(z_{\text{up}}^-) - V_{\text{inner}}(z_{\text{low}}^+)$ and $z_{\text{arg}} = (z - z_{\text{low}})/(z_{\text{up}} - z_{\text{low}})$. It is $a + b = 1$ for $V_{\text{trans}}(z_{\text{up}}^-) = V_{\text{outer}}(z_{\text{up}}^-)$, and we constrain a by

$$(11f) \quad \frac{\partial V_{\text{trans}}}{\partial z^-} \Big|_{z=z_{\text{low}}} = \frac{\partial V_{\text{inner}}}{\partial z^-} \Big|_{z=z_{\text{low}}},$$

where we find that $z_{\text{low}}^- = 0.06$ and $z_{\text{up}}^- = 0.13$ yield satisfactory agreement with DNS data.

5. COMPARISON WITH OTHER THEORIES

Compare to Emeis (2002) and Gryning (2007); highlight explicit knowledge on veering-profile → directional sheer;

Implications for **K-theory** (we now can consider that shear and stress are not necessarily perfectly aligned). → can we do something to infer a K-profile from these theoretical considerations?

6. CONCLUSIONS

Applications:

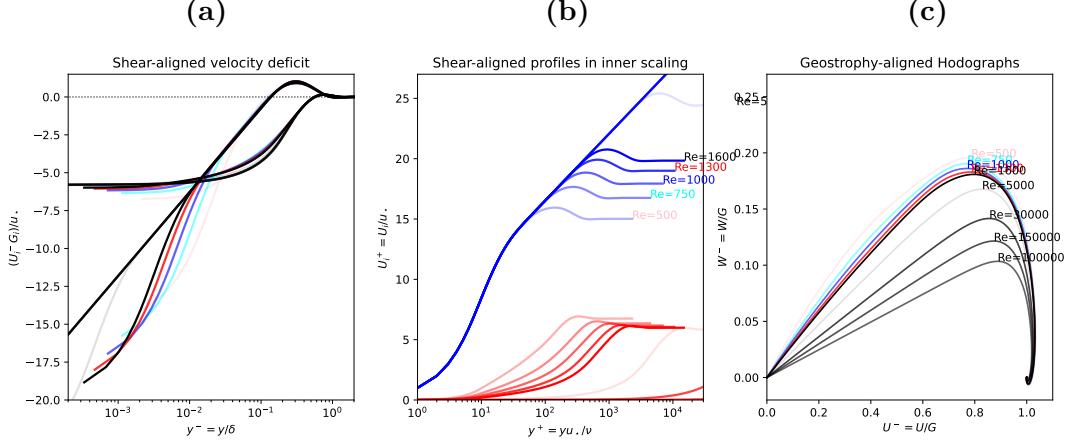

FIGURE 8. (a) Velocity deficit, (b) velocity profile in shear-aligned hodographs and (c) hodograph in geostrophy-aligned coordinates. Thick, solid lines show theory, dashed lines data from DNS.

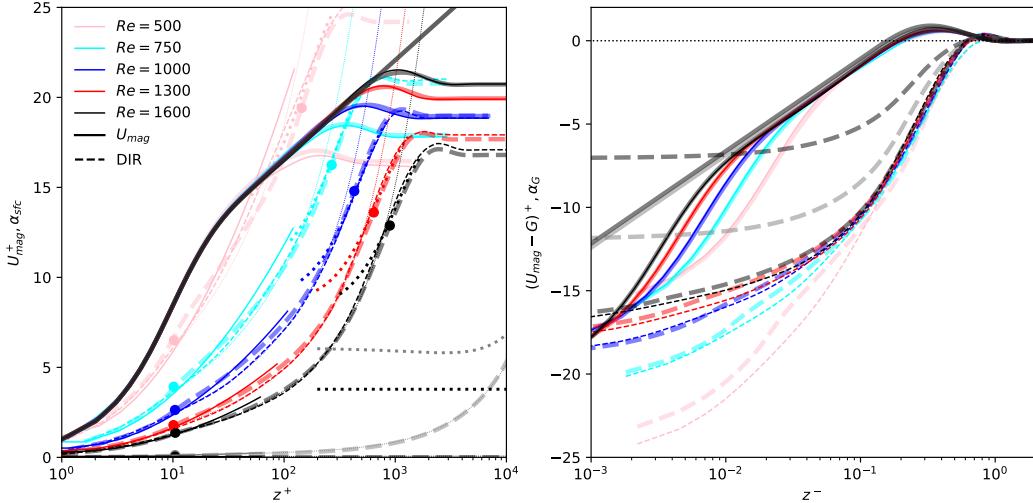

FIGURE 9. Total velocity and veering (in degrees) vs inner and outer height. Dashed lines show DNS data, thick lines are from semi-empirical theory.

- reference-shear for neutral profile approaches(systematic!) → wind engineering!
- initial condition for LES/DNS to eliminate/minimize inertial oscillation in Benchmark simulations

APPENDIX A. LAMINAR EKMAN SOLUTION WITH CONSIDERATION OF INNER LAYER

$$(12a) \quad \begin{pmatrix} \partial_t U \\ \partial_t W \end{pmatrix} = \begin{pmatrix} fW & + \nu \partial_z^2 U \\ -f(U - G) & + \nu \partial_z^2 W \end{pmatrix}$$

$$(12b) \quad \Rightarrow \partial_t(U + iW) = f(W - i(U - G)) + \nu \partial_z^2(U + iW)$$

In stationary conditions, this system is solved by

$$(12c) \quad \hat{u}(z) = U_\infty + e^{-\gamma z} [A \cos \gamma z + B \sin \gamma z]$$

$$(12d) \quad \hat{w}(z) = W_\infty + e^{-\gamma z} [-A \sin \gamma z + B \cos \gamma z]$$

where the constants U_∞, W_∞ set the top boundary condition and A and B set the bottom boundary condition. The most common boundary condition for a surface Ekman layer is $A = U_\infty = G$, $B = 0$, and $W_\infty = 0$. The lower boundary condition, however, neglects the existence of the surface layer, and it appears reasonable to define $A = cG$ where $c < 1$ is a constant that incorporates the increased shear in the surface layer. Given a 'matching height' z_{match} and normalized matching height $\xi = \gamma z_{\text{match}}$ in the upper part of the inner layer, we can match the Ekman profile to the inner layer by letting

$$(13) \quad \begin{aligned} u(z_{\text{match}}) \equiv u_{\text{match}} &= U_\infty + e^{-\xi} [A \cos \xi + B \sin \xi] \\ w(z_{\text{match}}) \equiv w_{\text{match}} &= W_\infty + e^{-\xi} [-A \sin \xi + B \cos \xi] \end{aligned}$$

$$(14) \quad \Rightarrow \begin{pmatrix} u_{\text{match}} - U_\infty \\ w_{\text{match}} - W_\infty \end{pmatrix} = e^{-\xi} \begin{pmatrix} A \\ B \end{pmatrix} \begin{pmatrix} \cos \xi & + \sin \xi \\ -\sin \xi & + \cos \xi \end{pmatrix}$$

(15)

Matching the profile at $\xi = 0$, one obtains $A = \Delta u_{\text{match}}$ and $B = -\Delta w_{\text{match}}$; and when the direction Ox is aligned with the geostrophic wind, we obtain the textbook-case $A = |\mathbf{G}|$ and $B = 0$.

Otherwise, choosing $B \neq 0$ allows to introduce a phase shift of the Ekman rotation with respect to the decay of the wind spiral. As, however, in our context, the thickness and position of the spiral can already be controlled by the eddy viscosity and an offset in ζ , here we let $B = 0$.
